Incremental Risk Charge Study

Tim Xiao

ABSTRACT

The incremental risk charge (IRC) is a regulatory requirement from the Basel Committee in response to the recent financial crisis. The earlier version of Basel IRC paper requires financial institutes to capture four risks: default, credit migration, significant credit spread changes, and significant equity price changes. However, the new guideline limits the risks to default and credit migration only. This paper proposes a model for computing incremental risk charge capital.

Keywords: Incremental risk charge (IRC), constant level of risk, liquidity horizon, constant loss distribution, concentration.

1 Introduction

The Basel Committee on Banking Supervision (see Basel [2009 a]) released the new guidelines for Incremental Risk Charge (IRC) that are part of the new rules developed in response to the financial crisis and is a key part of a series of regulatory enhancements being rolled out by regulators.

The constant level of risk assumption in IRC reflects the view that securities and derivatives held in the trading book are generally more liquid than those in the banking book and may be rebalanced more frequently than once a year (see Aimone [2018]). IRC should assume a constant level of risk over a one-year capital horizon which may contain shorter liquidity horizons. This constant level of risk assumption implies that a bank would rebalance, or rollover, its positions over the one-year capital horizon in a manner that maintains the initial risk level, as indicated by the profile of exposure by credit rating and concentration.

The current market risk capital rule is:

$$\begin{aligned} \text{Total market risk capital} &= \text{general market risk capital} \\ &+ \text{basic specific risk capital} \\ &+ \text{specific risk surcharge} \end{aligned} \tag{1}$$

where

$$\text{General market risk capital} = 3 \times \text{General_VaR}_{99\%}^{10\text{-day}}$$

$$\text{Basic specific risk capital} = 3 \times \text{Specific_VaR}_{99\%}^{10\text{-day}}$$

$$\text{Specific risk surcharge} = (m - 3) \times \text{Specific_VaR}_{99\%}^{10\text{-day}}$$

where m is the specific risk capital multiplier under regulators' guidance

In this paper, we present a methodology for calculating IRC. First, a Merton-type model is introduced for simulating default and migration. The model is modified to incorporate concentration. The calibration is also elaborated. Second, a simple approach to determine market

data, including equity, in response to default and credit migration is presented. Next, a methodology toward constant level of risk is described. The details of applying the constant level of risk assumption and aggregating different subportfolios are addressed. Finally, the empirical and numerical results are presented.

2 Simulation of Default and Credit Migration

The IRC encompasses all positions subject to a capital charge for specific interest rate risk according to the internal models with exception of securitization and nth-to-default credit derivatives. Equity is optional. For IRC-covered positions, the IRC captures default risk and credit migration risk only.

2.1 Simulation Model

Most of the portfolio models of credit risk used in the banking industry is based on the conditional independence framework. In these models, defaults and credit migration of individual borrowers depend on a set of common systematic risk factors describing the state of the economy. Merton-type models have become very popular. The Merton-type model (or standardized Merton model) is

$$z_i = \beta_i \phi + \sqrt{1 - \beta_i^2} \varepsilon_i \quad (3)$$

where

ϕ, ε_i	The independent standard normally random variables
ϕ	The systematic risk
ε_i	The idiosyncratic risk for issuer/obligor i
β_i	The weighted correlation reflecting the impact of systematic risk factor on issuer/obligor i.

z_i The normalized asset return or creditworthiness indicator for issuer/obligor i

This model becomes the most popular one in default and migration risk modeling and yields the core of the Basel II capital rule (see Heitfield [2003]).

2.2 Simulation model for multiple-liquidity-horizon subportfolios

Liquidity horizons are determined for each position to reflect actual practice and experience during periods of both systematic and idiosyncratic stresses. The total portfolio shall be divided into the subportfolios based on different liquidity horizons. Let's assume that there are two subportfolios with different liquidity horizons: 3 month and 6 month. To model different liquidity periods, one can use the above model (3) but calibrate different β_i 's, such as, β_{3m_i} and β_{6m_i} , for different periods.

Alternatively, one can also use a multiple-period model as:

$$z_{3m} = \beta_i \phi_{3m} + \sqrt{1 - \beta_i^2} \varepsilon_{3m_i} \quad \text{For 3 month} \quad (4)$$

$$z_{6m} = \beta_i \frac{\phi_{6m} + \gamma \cdot \phi_{3m}}{\sqrt{1 + \gamma^2}} + \sqrt{1 - \beta_i^2} \varepsilon_{6m_i} \quad \text{For 6 month} \quad (5)$$

where β_i is unique for different periods under issuer i and γ is an exponentially declining weight (see Dunn [2008]).

2.3 Calibration of β_i

The most popular approaches to calibrate the asset correlation are Maximum Likelihood Estimation or regression based on time series default data. Alternatively, in the new Basel Capital Accord, a formula for derivation of risk weighted asset correlation for corporate, sovereign, and bank exposures is given as (see Tasche [2004] and Basel [2003]):

$$\beta_i = 0.12 \times \lambda_i + 0.24 \times (1 - \lambda_i) \quad (6)$$

Where $\lambda_i = \frac{1 - e^{-50 \times PD_i}}{1 - e^{-50}}$

2.4 Concentration

The phenomenon we need to model is that concentration will result a higher IRC number, comparing to non-concentration case. Furthermore, the more concentration a portfolio has, the higher IRC result it generates. To achieve this, we model the effect of issuer and market concentration as well as clustering of default and migration by introducing another parameter, the *concentration parameter*.

Our methodology is based on a simple mechanism for coupling issuer/market concentrations to migrations and defaults. In the simulation framework (3) or (4) and (5), the probability of a migration or default increases with the asset volatility. Since the effect of increasing concentration within a sector is to increase the probability of migration/default events within that sector, we model increased concentration as an increase in the volatility of the systematic risk driver. All positions sensitive to that risk driver will have an increased probability of migration/default events occurring. The modified simulation model is

$$z_i = \beta_i (1 + \sqrt{|\rho_i|}) \phi_t + \sqrt{1 - \beta_i^2} \varepsilon_i \quad (7a)$$

Where ρ_i is the weighted concentration factor depending on correlation between issuer default and migration events and

$$\phi_t = \frac{x_t + \gamma \cdot x_{t-1} + \dots + \gamma^k \cdot x_{t-k}}{\sqrt{1 + \gamma^2 + \dots + \gamma^{2k}}} \quad (7b)$$

where if one uses (3), $\gamma = 0$ and $\phi_t = x_t = \phi$. Otherwise, γ is time declining weight and $x_t, \dots, x_{t-k}$ are independent standard normally random variables representing systematic risks in different time periods.

2.5 Calibration of ρ_i

$$\begin{aligned}
u_B^{BBB} &= \Phi^{-1} \left[\frac{1}{2} ((\Phi(z_{CCC}^{BBB}) + \Phi(z_B^{BBB})) \right] \\
u_{BB}^{BBB} &= \Phi^{-1} \left[\frac{1}{2} ((\Phi(z_B^{BBB}) + \Phi(z_{BB}^{BBB})) \right] \\
u_{BBB}^{BBB} &= \Phi^{-1} \left[\frac{1}{2} ((\Phi(z_{BB}^{BBB}) + \Phi(z_{BBB}^{BBB})) \right] \\
u_A^{BBB} &= \Phi^{-1} \left[\frac{1}{2} ((\Phi(z_{BBB}^{BBB}) + \Phi(z_A^{BBB})) \right] \\
u_{AA}^{BBB} &= \Phi^{-1} \left[\frac{1}{2} ((\Phi(z_A^{BBB}) + \Phi(z_{AA}^{BBB})) \right] \\
u_{AAA}^{BBB} &= \Phi^{-1} \left[\frac{1}{2} ((\Phi(z_{AA}^{BBB}) + 1) \right]
\end{aligned} \tag{8}$$

2.7 Calibration of transition matrix, default probability (PD), and loss given default (LGD)

The straight forward cohort approach is used to estimate transition matrices based on obligors' rating history, which has become the industry standard. The PD estimate is based on EDF data that is used for calculation of PD benchmarked against internal default history. Internal data is used for LGD parameter benchmarked against relevant external proxy data.

3 Credit Spreads and Equity Prices

After simulating default and migration of all issuers/obligors, we need to price every instrument in order to generate loss distributions. The question is whether we should simulate market data or not?

We assume all market prices/data are deterministic (flat) and use forward prices/data for valuation. The fat tail behavior and market correlations are embedded in the market. Keeping these parameters constant ensures we measure only P&L variation due to credit rating changes (migration or default) per IRC requirements. The selection of credit spreads or equity prices, however, should reflect the credit quality changes.

3.1 Credit spreads

All issuers/obligors shall be divided into credit groups based on geographies and sectors. Assume that the credit spreads for different ratings under each group are available. Then we can select associated credit spreads to price a bond or a CDS according to the creditworthiness simulation of the issuer/obligor.

3.2 Equity prices

In risk neutral world, the forward equity price at future time T is

$$E_T = E_0 e^{rT} \quad (9)$$

Where r is the risk free interest rate and E_0 is the today's spot equity price

If the issuer defaults at T , the equity price should be 0. If the issuer is upgraded or downgraded, the equity price should be larger or smaller than the risk neutral forward price $E_T = E_0 e^{rT}$. This is the phenomenon we are going to model:

$$E_T = \begin{cases} E_0 e^{rT} & \text{if no credit change} \\ 0 & \text{if default} \\ > E_0 e^{rT} & \text{if upgraded} \\ < E_0 e^{rT} & \text{if downgraded} \end{cases} \quad (10)$$

The underlying dynamic of Merton model is

$$dA_t = rA_t dt + \sigma_A A_t dW_t \quad (11)$$

Where A_t is the corporate asset value; r is the risk-free interest rate; σ_A is the asset volatility and W_t is the Wiener process.

Applying Ito's lemma, we have

$$A_T = A_0 \exp\left(rT - \frac{1}{2}\sigma_A^2 T + \sigma_A \sqrt{T} y\right) \quad (12)$$

where y denote the standard normal variable

The **Merton model** states that the equity of a company is a European call option on the asset of the company with maturity T and a strike price equal to the face value of the debt that will become due at T .

The payoff of Merton model is

$$E_T = \max(A_T - D, 0) \quad (13)$$

where D denotes the debt of the company.

The mathematical expression of Merton model is

$$E_0 = A_0 N(d_1) - e^{-rT} DN(d_2) \quad (14)$$

$$\text{where } d_{1,2} = \frac{\ln(A_0 / D) + rT}{\sigma_A \sqrt{T}} \pm \frac{1}{2} \sigma_A \sqrt{T}$$

We still use the BBB issuer as an example. Based on (8), (12), and (13), the equity price at T , if default occurs, is

$$E_T^{BBB \rightarrow D} = A_T^D - D = A_0 \exp\left(rT - \frac{1}{2} \sigma_A^2 T + \sigma_A \sqrt{T} u_D^{BBB}\right) - D = 0 \quad (15)$$

The equity price at T without credit quality changes is

$$E_T^{BBB \rightarrow BBB} = A_T^{BBB} - D = A_0 \exp\left(rT - \frac{1}{2} \sigma_A^2 T + \sigma_A \sqrt{T} u_{BBB}^{BBB}\right) - D = E_0 e^{rT} \quad (16)$$

We solve equations (14), (15), and (16) to get A_0 , σ_A , and D . Then, with the known A_0 , σ_A , and D , we can obtain any equity price at T under any credit rating according to (8) and (13). For instance, when the rating changes from BBB to A, the equity price at T is

$$E_T^{BBB \rightarrow A} = \max(A_T^A - D, 0) = A_0 \exp\left(rT - \frac{1}{2} \sigma_A^2 T + \sigma_A \sqrt{T} u_A^{BBB}\right) - D \quad (17)$$

4 Constant Level of Risk

The constant level of risk reflects recognition by regulators that securities/derivatives held in the trading book are generally much more liquid than those in the banking book, where a buy-and-hold assumption over one year may be reasonable. It implies that IRC should be modeled under

the assumption that banks rebalance their portfolio several times over the capital horizon in order to maintain a constant risk profile as market conditions evolve. Of course, we do not suggest that the constant level of risk framework be taken literally as a model of banks' behavior: clearly portfolios are altered on a daily basis, not simply held constant for some period then instantaneously rebalanced. Rather, we regard the rollover interpretation as being a **reasonable approximation** to the way banks manage their trading portfolios over a certain horizon. In general, one should model constant level of risk instead of constant portfolio over one year capital horizon.

The liquidity horizon for a position or set of positions has a floor of **three months**. Let us use three months as an example. We interpret constant level of risk to mean that the bank holds its portfolio constant for the liquidity horizon, then rebalances by selling any default, downgraded, or upgraded positions and replaces them so that the portfolio is returned to the level of risk it had at the beginning. The process is repeated 4 times over the capital horizon resulting 4 independent and identical loss distributions. The one year constant level of risk loss distribution is the convolution of 4 copies of the three month loss distribution. **In Monte Carlo context, this can be modeled by drawing 4 times from the single period loss distribution measured over the liquidity horizon.**

The total PnL is the summary of these 4 random draws.

The final P&L for the path will be the summary of all losses and profits.

Figure 2 Constant level of risk

In addition, one needs to consider the reinvestment of all cash flows realized during the liquidity horizon and rollover of expired deals.

5 Aggregation and Time Horizon Correlation

First we need to divide the portfolio into the subportfolios based on liquidity horizons. If there is only one single-liquidity-horizon subportfolio, the rebalance at the end of each liquidity horizon washes out the time horizon correlation. However, if there are multiple subportfolios, the time horizon correlations need to be addressed.

There are two approaches to achieve the correlative aggregation: copula approach or correlation matrix approach.

5.1 Copula approach

We conduct the second Monte Carlo simulation by generate 4 standard normal random draws for scenario j : $x_1^j, x_2^j, x_3^j, x_4^j$. These random draws represent a Monte-Carlo path.

5.1.1 Three-month Subportfolio

The P&L distribution of three-month subportfolio is PL_{3m} . The four draws of loss distribution are $PL_{3m}(\Phi(x_1^j)), PL_{3m}(\Phi(x_2^j)), PL_{3m}(\Phi(x_3^j)), PL_{3m}(\Phi(x_4^j))$, where Φ is the accumulative normal. The total P&L of the three-month subportfolio for scenario j is

$$PL_{total_3m}^j = \sum_{i=1}^4 PL_{3m}(\Phi(x_i^j)) \quad (18)$$

5.1.2 Six-month Subportfolio

The P&L distribution of the six-month subportfolio is PL_{6m} . We can calculate correlation $\rho(PL_{3m}, PL_{6m})$ between PL_{3m} and PL_{6m} using Pearson product-moment. The two correlated random draws are $x_{6m-1}^j = \rho(PL_{3m}, PL_{6m})x_1^j + \sqrt{1 - \rho(PL_{3m}, PL_{6m})^2}x_2^j$ and $x_{6m-2}^j = \rho(PL_{3m}, PL_{6m})x_3^j + \sqrt{1 - \rho(PL_{3m}, PL_{6m})^2}x_4^j$. The two draws of loss distribution are $PL_{6m}(\Phi(x_{6m-1}^j))$, $PL_{6m}(\Phi(x_{6m-2}^j))$. The total P&L of the six-month subportfolio for scenario j is

$$PL_{total-6m}^j = \sum_{i=1}^2 PL_{6m}(\Phi(x_{6m-i}^j)) \quad (19)$$

Summing up (18) and (19), we can get the total P&L for scenario j as

$$PL_{total}^j = PL_{total-6m}^j + PL_{total-3m}^j \quad (20)$$

5.2 Correlation matrix approach

Based on the four 3-month independent identical loss distributions: $PL_{3m}, PL_{3m}, PL_{3m}, PL_{3m}$, and two 6-month independent identical loss distributions: PL_{6m}, PL_{6m} , we can construct a 6×6 pair-wise sample correlation matrix Σ . Applying the Cholesky decomposition to the correlation matrix Σ , we have $\Sigma = LL^T$, where L is a lower triangular matrix.

We conduct the second Monte Carlo simulation by generating 4 independent standard normal random draws: $x_1^j, x_2^j, x_3^j, x_4^j$ for the four 3-month periods in a year and 2 independent standard normal random draws x_5^j, x_6^j for the two 6-month periods to construct a path/scenario j. The random draw vector is $X = [x_1^j \ x_2^j \ x_3^j \ x_4^j \ x_5^j \ x_6^j]$. We can obtain correlative random draw vector

$$\tilde{X} = [\tilde{x}_1^j \ \tilde{x}_2^j \ \tilde{x}_3^j \ \tilde{x}_4^j \ \tilde{x}_5^j \ \tilde{x}_6^j] \text{ by } \tilde{X}^T = L \times X^T \quad (21)$$

The total P&L for scenario j is

$$PL_{total}^j = PL_{total_3m}^j + PL_{total_6m}^j = \sum_{i=1}^4 PL_{3m}(\Phi(\tilde{x}_i^j)) + \sum_{i=5}^6 PL_{6m}(\Phi(\tilde{x}_i^j)) \quad (22)$$

The final IRC will be 99.9% VaR based on distribution PL_{total}^j . In general, the correlation matrix approach is more generic and can be easily extended to any number of subportfolios.

6 Numerical and Empirical Results

The above methodology has been implemented. The empirical study shows the results on P&L distributions, numerical stability & convergence, concentration effect, and capital impact.

The loss distributions for the testing portfolio are shown in Figure 3 and 4.

Figure 3 Histogram of loss distribution at 3 month

Figure 4 Histogram of loss distribution at 1 year

6.1 Convergence study

People normally believe that 50,000 simulations provide sufficient stability to measure the 99.9th percentile loss required for the regulatory IRC measure. However, our study shows that 50,000 paths are not convergent. Actually 100,000 simulations are needed to archive a better numerical stability and convergence. The results are shown in Table 1

Table 1 convergence results

Scenarios	IRC	Diff from previous	Diff from average
8,000.00	102.31		-1.51%
10,000.00	103.56	1.23%	-0.30%
20,000.00	100.44	-3.01%	-3.30%
40,000.00	100.71	0.27%	-3.04%
60,000.00	110.01	9.23%	5.91%
80,000.00	105.22	-4.35%	1.30%
100,000.00	104.90	-0.31%	0.99%

120,000.00	103.66	-1.18%	-0.20%
140,000.00	103.96	0.28%	0.08%
160,000.00	103.61	-0.33%	-0.25%
180,000.00	105.23	1.56%	1.31%
200,000.00	103.14	-1.99%	-0.71%
Average	103.87		

6.2 Concentration study

The purpose of this section is to demonstrate that the model (7) can reflect issuer and market concentrations. To simplify our tests, we assign all issuers with the same concentration factor ρ . It is shown that the IRC increases according to the increasing of ρ , up to 30% in table 2.

Table 2 Concentration study

Scenarios	ρ	IRC	Diff from 0 concentration
100,000	0	104.90	0
100,000	0.2	116.97	11.50%
100,000	0.4	122.37	16.66%
100,000	0.6	128.49	22.48%
100,000	0.8	132.83	26.63%
100,000	1	137.23	30.82%

6.3 Capital impact

The capital impact can be measured as the ratio between IRC and specific risk surcharge. The results significantly depend on the composition of a portfolio and the specific risk multiplier of a financial institution set by the regulator. The ratio of our testing portfolio is 5.8.
