Abstract: We assess if asking victims about the places where crimes happen leads to estimates of ‘crime in place’ with better measurement properties. We analyse data from the Barcelona Victimization Survey (2015 to 2020) aggregated in 73 neighbourhoods using longitudinal quasi-simplex models and criterion validity to estimate the quality of four types of survey-based measures of crime. The distribution of survey-based offence location estimates, as opposed to victim residence estimates, is highly similar to police-recorded crime statistics, and there is little trade off in terms of the reliability and validity of offence location and victim residence measures. Estimates of crimes reported to the police show a better validity, but their reliability is lower and capture fewer crimes.

1. Introduction

Police-recorded crimes have long been the main data source used by researchers, crime analysts and policy makers to document community differences in crime risk and evaluate crime prevention strategies. While the accessibility and versatility of police-recorded crime data has allowed its usage in a wide variety of contexts, it has also been subject to criticism due to the substantial presence of measurement error resulting from the combined influences of victims' under-reporting and inconsistencies in recording practices across police jurisdictions (Coleman and Moynihan 1996; HMIC 2014; Skogan 1977; Xie and Baumer 2019). Studies have demonstrated that the analysis of community differences in crime from police data may be affected by variations in the magnitude of the 'dark figure of crime' (i.e., crimes that are not recorded in police statistics) across neighbourhoods (Buil-Gil, Medina et al. 2021; Goudriaan et al. 2006), with substantially more under-coverage in some small geographic areas than others (Buil-Gil, Moretti et al. 2021; Nogueira Melo et al. 2020). This is problematic, calling into question the conclusions of many studies that examine the spatial distribution of crime using police data.

As a result, researchers are increasingly using crime surveys to obtain 'unbiased' estimates of crime and to measure variation across geographic areas (Buelens and Benschop 2009; D'Alò et al. 2012; Fay and Diallo 2012; Kershaw and Tseloni 2005; McVie and Norris 2006). However, survey-based crime data are not error-free. Like any other sample-based survey, crime surveys are affected by measurement error arising from the data collection process and the sampling design. This may include the effects of poor question wording, limitations with the questionnaire design, as well as inadequate training of survey personnel, sampling bias and non-response bias (Biemer 2009; Lohr 2019; Rosenbaum and Lavrakas 1995). Crime estimates also suffer from unique errors arising from victims' memory failures, social-desirability bias, underestimation or exaggeration of situations, and telescoping, contributing to substantial systematic bias and low reliability (Lohr 2019; Schneider 1981; Skogan 1975).

However, there is another important problem affecting the quality of crime survey estimates in relation to the spatial distribution of crime, which has so far received limited attention. Estimates of crime in geographic areas derived from surveys tend to be unduly based on the places where victims live ('area victimisation rates'), not the places where crimes happen ('area offence rates'). Based on estimates from the British Crime Survey 2002/03, Hodgkinson and Tilley (2007) observed that more than 27% of crimes take place further than 15 minutes walking distance from the victim's household, and these tend to concentrate in city centres and business districts.

This distinction complicates efforts to compare and combine the estimates of crime from police and survey data (Bottoms and Wiles 1997), and the extent to which survey-based estimates of area victimisation rates can be treated as a valid measure of crime in place is currently unknown. While survey-based estimates of area victimisation rates may provide valid measures of household crime in residential neighbourhoods, they likely fail to accurately estimate crime in those places where crime is most prevalent. For example, in Barcelona, Spain, more than 60% of crimes recorded in the 2019 local victimization survey happened outside the victims' neighbourhood of residence, and these were highly concentrated in the city centre (González Murciano and Murrià Sangenís 2020).

In this paper we use data from six rounds of the Barcelona Victimization Survey (between 2015 and 2020) aggregated at the neighbourhood level to document the extent of this problem. This survey is unique in its design, including a series of questions about the geographic area where each crime takes place, in addition to the more standard items about the victims' neighbourhood of residence and whether crimes are reported to the police. We assess which survey-based measure of crime (i.e., victim residence or offence location) show better measurement properties as a measure of crime across geographic areas. We also examine the effect of restricting the focus to the subset of offences that are reported to the police, providing a more direct comparison with police recorded crime figures. We use longitudinal quasi-simplex models and criterion validity to estimate the quality of estimates of crime in neighbourhoods obtained from the Barcelona Victimization Survey, comparing these to measures of crime recorded by the police over the same six-year period.

2. Background

In response to the growing concern that police-recorded crime data may not provide valid measures of crime for comparisons across countries (Aebi 2010; von Hofer 2000), regions/states (Fay and Diallo 2012; Martin and Legault 2005; Pina-Sánchez et al. 2021), neighbourhoods (Buil-Gil, Medina et al. 2021) and micro places (Brantingham 2018; Nogueira Melo et al. 2020), a nascent body of literature has sought to rely on survey data to obtain estimates of crime in geographic areas. For example, Kershaw and Tseloni (2005) used regression models from British Crime Survey data and area-level administrative records of age, ethnic groups, poverty and housing to estimate crime in local areas. Similarly, Buelens and Benschop (2009) applied model-based small area estimation to produce estimates of violent crime incidence in 25 police zones in Netherlands from survey data. Small area estimation methods were also used by D'Alò et al. (2012) to estimate violence against women across regions in Italy, and by Fay and Diallo (2012) to estimate rates of

different offences in US states. More recently, Buil-Gil, Moretti et al. (2021) demonstrated how regression parameters from the Crime Survey for England and Wales and known demographic values from the Census could be used to generate synthetic crime data in small geographic areas in Manchester (a similar approach is followed in Akpinar and Chouldechova 2021). Also in the UK, the Office for National Statistics uses data from the Crime Survey for England and Wales to calculate estimates of prevalence and incidence of crime types at the level of police force areas.¹

Whilst this research has been important in advancing our understanding of the geographical distribution of victimisation rates, they may fail to accurately capture the spatial distribution of crimes *where they happen*. Therefore, in their attempt to avoid the measurement error present in police data, survey-based crime estimates may be affected by different forms of errors. With the exception of household offences, it is likely that a large proportion of crimes do not occur within the immediate vicinity of the victims' household. For example, González Murciano and Murrià Sangenís (2020) show that the majority of crime victims are victimised outside of their residential neighbourhood, and crimes are highly concentrated in city centres (see also Hodgkinson and Tilley, 2007). This leaves open the possibility of misclassification errors if the area where the offence took place does not correspond to the area where the victim lives.

However, the scale of this problem is currently unclear. In the absence of survey questions seeking to identify the specific places where crimes happen we can only speculate about the extent of the problem. None of the major victimization surveys offer this information. In Table A1 (in the appendix) we report the questions about places where crimes happen in eight of the most widely used crime victimization surveys.² The national crime surveys in the United States, Mexico and Chile ask participants to specify the municipality where each crime incident occurred, but this information is not included in the open access of the US National Crime Victimization Survey. In the cases of England and Wales, Scotland, Canada, New Zealand and the International Crime Victims Survey, the questionnaire asks participants whether the crime took place near home or near the place of work, but the location of the place of work is not included in the surveys and the location of the household can only be accessed through a special licence access to the surveys.

¹ For example, the Office for National Statistics published estimates of rates for nine types of crimes (<https://www.ons.gov.uk/peoplepopulationandcommunity/crimeandjustice/adhocs/008928crimesurveyforenglandandwalesincidenceandratesforheadlinecrimecategoriesbypoliceforceareaendingmarch2016toyearendingmarch2018>) and estimates of risk of personal crime, household crime and all crime (<https://www.ons.gov.uk/peoplepopulationandcommunity/crimeandjustice/adhocs/12032crimesurveyforenglandandwalescsewsestimatesofpersonalandhouseholdcrimeantisocialbehaviourandpublicperceptionsbypoliceforceareaendingmarch2020>) at the level of police force areas.

² An overview of the main crime victimization surveys worldwide can be found at the Atlas of the Centre of Excellence in Statistical Information on Government, Crime, Victimization and Justice of the United Nations Office on Drugs and Crime (<http://www.cdeunodc.inegi.org.mx/index.php/mapa-2/>).

None of the surveys examined includes a question about the address or neighbourhood where incidents happen, and only some of them probe about the city where it happened. Thus, available data from these national and international crime surveys do not allow the estimation of accurate area offence rates at levels below municipality.

To the best of our knowledge, the Barcelona Victimization Survey is the first regular public survey which probes respondents about the precise location where crime incidents take place, enabling survey administrators to code the specific longitude and latitude coordinates of the crime event (or at least the neighbourhood when specific places cannot be located). The availability of this information brings a unique opportunity to assess the magnitude of potential misclassification errors arising from the use of victim location data to estimate area offence rates. The Barcelona Victimization Survey is unique in recording information about the respondents' neighbourhood of residence, neighbourhood where each crime happens, and whether each crime is reported to the police. Thus, it makes it possible to investigate the validity and reliability of different area-level estimates of crime in place, and comparing these with police-recorded crime data.

We expect survey-based estimates of non-residential property crimes and violence incidents where they happen to be more valid and reliable measures of crime in place than survey-based area victimization estimates. However, this may not necessarily be the case for residential property crimes which take place in areas where victims live. Moreover, survey-based estimates of crimes reported to the police (whether offence or victim-location based) are expected to be closer to police statistics than any other measure. However, estimates of crimes reported to the police may be affected by the uncertainty arising from the small samples of crimes recorded in small areas (Rosenbaum and Lavrakas 1995). Previous research has shown that crime in Barcelona is highly concentrated in the 'old quarter' (González Murciano and Murrià Sangenís 2020; Maldonado-Guzmán et al. 2021), which is characterised by very large concentrations of tourist, hotels, restaurants, museums, bars and clubs, but not necessarily a larger population density (Graells-Garrido et al. 2020; Gutiérrez et al. 2017). As a result, we would expect survey-based estimates of offence locations to show large concentrations of crime in the city centre, while this may remain hidden when we analyse survey-based estimates of area victimizations.

Importantly, having multiple measures of crime available for the same areas allows us to examine the extent of other potential problems affecting the accuracy of crime estimates in local areas (Lohr 2019; Schneider 1981). For example, whether victims' non-recall and memory loss contribute to systematic non-response biases in questions about offence locations, and whether

victims who suffer a crime in their local areas systematically answer this question more frequently, or more accurately, than victims who suffer crime incidents in other places.

3. Data and modelling strategy

Data description

We analyse data from six rounds of the Barcelona Victimization Survey (2015 to 2020) aggregated in 73 neighbourhoods. Barcelona is the second largest city in Spain, with a population of 1.6 million residents (3.2 million in the Barcelona Metropolitan Area). Our units of analysis are Barcelona neighbourhoods, with an average population of 22,608 residents (ranging from 686 residents in la Clota neighbourhood to 58,642 in la Nova Esquerra de l'Eixample).

The Barcelona Victimization Survey is one of the oldest crime surveys in Europe, and it has recorded data annually since 1984. Its sampling frame is all Barcelona residents aged 16 or more. Citizens aged 16 to 64 fill the questionnaire via a web survey, while those aged 65 or more answer the questionnaire through Computer-Assisted Telephone Interviewing (CATI). The survey is designed to select stratified random samples based on the district of residence, sex, age groups and nationality of respondents, but sample sizes vary considerably across years depending on budget constraints (see Table A2 in the appendix). In order to mitigate the effect of small sample sizes in neighbourhoods, we aggregate data every two years (i.e., 2015-16, 2017-18 and 2019-20).³

Participants are asked questions about their perceptions of security and disorder, confidence in policing and other neighbourhood perceptions, as well as screening questions about crime victimization in the last year (e.g., burglary, vehicle crime, robbery, theft, mobile phone theft, violence, threats, sexual violence, fraud). Importantly, and unlike other crime surveys, the Barcelona survey also includes questions designed to uncover the precise location where each incident took place with the following wording: “Please, write down the street where it happened. We need to know the nearest possible street which crosses the place where it happened, or at least a nearby reference point to locate the neighbourhood where it happened. Enter the street and building number, or a nearby place or intersection of streets”.⁴

³ The Barcelona Victimization Survey microdata is available from the Public Opinion Poll Register of the Barcelona City Council (<https://ajuntament.barcelona.cat/en/administrative-information/public-opinion-poll-register>). Further, data about respondents' neighbourhood of residence was gathered from the Barcelona Institute of Regional and Metropolitan Studies through a freedom of information request.

⁴ Translation of the original question in Catalan: “Si us plau, anoti el carrer on li va passar. Necessitem el carrer més proper que creua o que li fa cantonada o almenys algun punt proper de referencia que permeti situar la zona on es troba aquesta adreça només per tal de poder-lo clasificar en un barri: Tipus de via, nom, número, lloc/cruïlla.”

Every time respondents report they suffered a crime, the questionnaire probes the number of times it happened in the last year. Then, a series of questions are asked about each crime incident, including the time and place of the event, and whether it was reported to the police. The survey imposes a cap of three crimes per crime type before asking follow-up questions about each event. This is not expected to be a major issue since only 1.3 percent of respondents, or 3.9 percent of victims, reported suffering more than three crimes in at least one crime category. In this study we aggregate incidents to three types of crimes to avoid geographic areas with no crimes recorded:

- **Property (personal):** includes theft, attempted theft, theft of bag, attempted theft of bag, theft of mobile phone, attempted theft of mobile phone, theft of other objects carried by person, and attempted theft of other objects carried by person.
- **Property (vehicle and household):** includes theft from inside vehicle, theft of vehicle parts, theft of vehicle, attempted vehicle crime, burglary, attempted burglary, burglary of second household, attempted burglary of second household, non-violent robbery of establishment, and non-violent attempted robbery of establishment.
- **Violence:** includes robbery with violence, attempted robbery with violence, robbery with violence against establishment, attempted robbery with violence against establishment, assault, attempted assault, and threat of violence.

We used the survey weights provided by survey administrators, which are computed to adjust for non-response and to match the sample to population proportions based on the district of residence⁵ and demographic characteristic of respondents, to calculate the weighted sum of crimes in areas. These weights are calculated to adjust individuals to population proportions so the mean of weights is 1, but these do not adjust the sample to population totals. Thus, the scale of our survey-based estimates of crime will vary substantially from that in reality, but the rank and distribution across areas are expected to be maintained. We return to this point in the discussion.

We also accessed data about crimes reported to Mossos d'Esquadra, the police force of Catalonia, between 2015 and 2020 through a freedom of information request, enabling direct comparisons of survey estimates with police statistics.

In order to understand the impact of asking about the offence location and crime reporting on crime estimates in place, we define four different ways of measuring a crime depending on

⁵ Districts are larger geographic unit than neighbourhoods and smaller than local authorities. In Barcelona city there are 10 districts.

whether this is based on the victim residence or offence location, as well as whether the crime was reported to the police or not. These four ways of measuring crimes are:

- **Victim residence:** crimes suffered by the residents of a neighbourhood during the last 12 months.
- **Offence location:** crimes that took place in a neighbourhood (suffered by residents and non-residents) during the last 12 months.
- **Victim residence (reported):** crimes suffered by the residents of a neighbourhood during the last 12 months that were reported to the police.
- **Offence location (reported):** crimes that took place in a neighbourhood (suffered by residents and non-residents) in the last 12 months that were reported to the police.

Modelling approach

We use different strategies to estimate the data quality of our four measures of crime. We use descriptive analyses to compare the average of crime counts recorded in neighbourhoods using the four different approaches. We also use police-recorded crimes as a criterion, comparing the geographical distributions and correlations of survey-based crime estimates and police data to study the extent to which estimates of crime obtained from survey data resemble police-recorded crime statistics.

We then exploit the design of the data (i.e., repeated measures of the same crime types based on different approaches) to build a series of statistical models to estimate data quality. We start by estimating the reliability of these measures using the quasi-simplex model (henceforth QSM; Alwin 2007; Cernat et al. 2021; Heise 1969; Wiley and Wiley 1970). This model uses repeated measures of the same concept in order to estimate reliability (Figure A1 in the appendix). This approach enables the estimation of reliability using only one measure collected at least three times in line with the Classical Test Theory (Lord and Novick 1968).

The model can be decomposed into two parts. Firstly, a measurement model defines the relationship between the observed variable y_t , measured at each point in time t , and an observed latent variable, T_t :

$$y_t = T_t + \epsilon_t$$

The difference between the observed and the latent variable is the residual of this relationship and an estimation of random error, ϵ_t . Second, the QSM includes a structural model defined by an auto-regressive relationship:

$$T_t = \beta_{t,t-1}T_{t-1} + \zeta_t$$

Here, the latent score at each point in time, T_t , is explained by the measure at the previous time point, T_{t-1} . The strength of this relationship, estimated using $\beta_{t,t-1}$, is the stability of the concept in time, while the residual, ζ_t , represents the time-specific variation. This model enables the estimation of the reliability of each measure of crime in line with the Classical Test Theory (Lord and Novick 1968). The quasi-simplex model estimates the reliability as the proportion of variation explained by the trait, T_t , from the total variance of the observed variable.

In order to estimate the model, further restrictions are needed, especially in relation to the random error, ϵ_t . Two different approaches have been proposed for this: either to restrict the reliability in time (Heise 1969) or to restrict the variance of the residual (Wiley and Wiley 1970). Here we choose the latter as it enables the estimation of change in time of reliability. That being said, prior empirical results have highlighted that the two restrictions lead only to small differences (Alwin 2007; Cernat et al. 2021). We run this model separately for each crime type and each type of measurement, resulting in a total of 12 models.

In addition to estimating reliability, the data also enables the estimation of validity. We define validity as that proportion of variance that measures the concept of interest and is not affected by random error or by variance specific to one particular way of collecting the data. We label the proportion of variance associated with each way of collecting data as the “method effect”, as it refers to that part of the variance that does not measure the concept of interest but is systematic (i.e., consistent over multiple measurements).

To estimate the validity, method effect, and random error, we use a Multi Item Quasi-Simplex Model (MI-QSM). This combines the longitudinal QSM with the a Multitrait Multimethod model (Campbell and Fiske 1959; Saris and Andrews 1991) – a model used in psychometrics and survey research to estimate reliability and validity when multiple concepts (or “traits”) are measured using multiple approaches (or “methods”). Here we define as a “method” each of the different ways to estimate crime in place from our survey data and as a “trait” each of the different crime types (Figure A2 in the appendix).

The MI-QSM also has a measurement model and a structural model. This time, we have multiple variables at each point in time, t , for each of the m methods used. These observed variables are explained by two latent variables. The estimate of the concept of interest is defined by T_t , which varies across time, t . The method effect, M_m , is estimated separately for each way of measuring crime, m , but is treated as stable in time. The residual, ϵ_{mt} , represents the unexplained

variance, or random error of the question. Together, these lead to the following measurement model for the observed variable, y_{mt} :

$$y_{mt} = T_t + M_m + \epsilon_{mt}$$

The same autoregressive structural model defined for the QSM is used to enable the change in time of the trait:

$$T_t = \beta_{t,t-1}T_{t-1} + \zeta_t$$

We run this model separately for each of the three types of crime: personal property crime, property crime against a household or vehicle, and violent crime.

Using this model, we can decompose the variation of each observed variable into three parts. The variance explained by T_t represents the “valid” portion of variance. The variance explained by M_m represents the “method” effect, or that proportion of variance which is specific to a way of measuring crime and is stable in time. We can also consider this as lack of validity (i.e., consistent variance but not associated with the concept of interest). Finally, the proportion of variation that is not explained by T_t or M_m , ϵ_{mt} , is an estimate of the random error.

The QSM and the MI-QSM can be estimated using standard structural equation modelling software. We estimate the models using R 4.0.5 (R Core Team 2021) and the ‘blavaan’ package (Merkle and Rosseel 2018) with ‘Stan’ for estimation. For the Bayesian estimation we use eight chains, a burn-in of 50,000 iterations and a sample of 5,000 to calculate the estimates.⁶ In order to help with the estimation, and avoid skewed distributions, we add 1 and take the log of the number of crimes. All codes are available from a Github repository (anonymised repository: https://anonymous.4open.science/r/crime_long_me/).

4. Results

Looking first at the raw bivariate correlations between our four survey-based estimates of crime and police-recorded crime in neighbourhoods (Figure 1), we find remarkably high correlations when using the new offence location-based estimates. This ranges from a low of 0.8 for household and vehicle property offences to almost 0.95 when personal property offences are considered. Importantly, the correlation is only marginally lower for property offences when we

⁶ As a sensitivity analysis, we re-run some of the models in Mplus software (Muthén and Muthén 2017) using Maximum Likelihood estimation. Results (not shown) are similar, but the Maximum Likelihood can lead to negative variances (i.e., Heywood cases) when variances are small. Thus, we report the Bayesian results for the QSM and MI-QSM.

restrict the focus to the subset of these offences that are reported to the police. The correlation is noticeably lower when reported incidents of violence are considered, although this does not seem to be a result of uneven reporting rates (on average, 21.9% of violent incidents were reported to the police, compared with 22.5% for personal property offences and 31% of household/vehicle offences). By contrast, the correlations are lower when the victim's residential location is used, with a correlation of around 0.8 for violence and personal property offences, and under 0.75 for household and vehicle property offences.

As expected, we observe a much closer correspondence between the estimates when household/vehicle property offences are considered, which is likely the result of the high proportion of these offences that occur within the victim's residential location (70.9% of property household/vehicle offences happened in the area of residence, compared with 53.9% of violent crimes and 30.7% of personal property offences).

We also observe that correcting the measurements by restricting them only to those crimes that were reported to the police leads to lower correlations with police data both for the location- and residence-based measures. It appears that attempting to make the two data sources more similar by asking respondents about reporting to the police has a limited utility. This may be due to the introduction of other types of measurement error in the reporting questions, such as memory effects or social desirability, but will also be due to the small sample sizes of crimes reported to the police recorded in the survey. Overall, the average number of crimes recorded in the survey in neighbourhoods is much smaller when we restrict the measurement to crimes reported to the police (see Figure A3 in the Appendix). It is important to note, however, that as visualised by the 95% confidence intervals some of the differences described here, especially those related to household and vehicle property offences, are not significant, although this may be due to the small number of neighbourhoods under study (i.e., our sample is 73 areas).

Figure 1. Correlation with the police data by topic and “method” in the data aggregated for 2015-2020. Variables were transformed prior by adding 1 and taking the log.

The close correspondence between the new offence-based estimates and police-recorded crime can be clearly seen when we plot the spatial distribution of crimes on a map (Figure 2).⁷ Whilst all four survey estimates correctly locate the majority of incidents in the city centre and ‘old quarter’, the victim-based estimates tend to identify a substantially higher proportion of offences occurring throughout the rest of the study area, which is not shown in the police data. By contrast, the offence-based estimates more closely resemble police recorded crime data, with relatively fewer offences occurring in the surrounding areas.

For violent crimes and personal property crimes, the two maps based on offence location survey data and police records are highly alike, while survey-based victim residence maps fail to show the ‘hot spots’ of crime in the city centre. Contrary to expectations, however, offence location maps visualised from all survey-recorded crimes (reported and not reported) resemble more closely police-recorded crime statistics than maps produced from reported crimes only. This is likely the effect of the small sample of crimes reported to the police in the survey (Figure A3 in the Appendix). Examined visually, we can again see the close correspondence between all four

⁷ Here we use linearly transformed crime counts ranging from 0 to 100 to allow for comparisons across datasets with different scales. These are transformed as $\frac{\hat{\theta}_d - \min(\hat{\theta})}{\max(\hat{\theta}) - \min(\hat{\theta})} \times 100$, where $\hat{\theta}_d$ is an estimate of crime in a given area d .

estimates of household and vehicle property crime, although the offence location map still appears to show the closest distribution to police-recorded crimes.

Comparisons with police-recorded crime data suggest potential reductions in area-based misclassification errors if survey respondents are asked to provide details of the location where incidents occurred. To assess whether this has implications for the validity and reliability of our survey estimates, we turn our attention to the results of the longitudinal quasi-simplex models. Figure 3 reports the reliability estimates from the 12 QSM (three topics x four ways to measure them). Here, we find comparatively little evidence of a reliability trade off when asking respondents to locate incidents, with similarly high reliability estimates of around 0.9 using either victim residential location or offence location estimates. Perhaps unsurprisingly, the reliability estimates are somewhat lower when restricting the focus to those offences that are reported to the police, particularly when violent offences are considered (with fewer than one in four violent offences reported to the police).

Figure 3. Reliability estimates by topic, type of measure and wave based on the quasi-simplex model

We also show the variance decomposition based on the three MI-QSM (Figure 4). We define ‘validity’ as the proportion of variance due to the trait, ‘lack of validity’ as the proportion of variance due to the method (or the way of asking the question), and ‘random error’ as the unexplained variance in the observed scores. Results from the MI-QSM models (Figure 3, and Tables A3 and A4 in the Appendix) indicate that offence location measures have a higher overall quality (i.e., trait variance) compared to victim measures. This seems to be mainly due to the method effect which, in the cases of household and vehicle property crime and violence, is higher for victim residence measures than offence location measures. Once again, in the case of personal property crime, there is little difference between using offence location and victim residence measures. Importantly, according to these results, using the survey-based measures restricted to crimes reported to the police appears to lead to a moderate improvement in data quality, especially due to an overall decrease in the method effect. Thus, based on these results, the estimates of offence location-based crimes reported to the police appear to be the best way (in terms of data validity) to measure the three types of crime (see also Table A3 in the Appendix). We also find that the proportion of variance associated with the method is stable across the three time periods studied, pointing to the robustness of our findings.

Figure 4. Variance decomposition by trait, method and random error for the three topics and three ways of measuring crime

5. Discussion and conclusions

Crime surveys are increasingly used for research and policy making as they can bypass some of the limitations of police records. One example of this move towards the use of crime surveys is the increase in research applying small area estimation to crime counts in geographic areas (Buelens and Benschop 2009; Buil-Gil, Medina et al. 2021; D’Alò et al. 2012; Fay and Diallo 2012). In this paper, we discuss two important aspects of survey-based estimates of crime that can have substantial impacts on results: whether estimates refer to the offence location or victim residence, and whether these reflect all crimes or those reported to the police.

We argue that a more nuanced understanding of the measures of crime included in sample surveys is needed, and the assumption that the respondents’ area of residence equates the place where crimes happen may be incorrect. From previous research we know that large proportions of crimes take place outside the victims’ area of residence (González Murciano and Murrià Sangenis 2020; Hodgkinson and Tilley 2007) and tend to concentrate in certain places (Andresen and Linning 2012; Weisburd 2015). Thus, the assumption that estimates of ‘places where victims

live' can be interpreted as 'crimes in place' is dubious. Fear of crime researchers realised years ago that analysing the geographic distribution of emotions about crime based on areas where survey respondents live vary substantially from the areas where events of fear actually concentrate, thus suggesting the use of place-based methods to capture fear of crime where it happens (Solymosi et al. 2015). A similar movement is needed in research using survey data to estimate crime in place. In this research we investigate how data quality can be influenced when the crime location and police reporting are measured in crime surveys.

The descriptive analysis has highlighted that survey area-level crime location estimates have a substantially higher correlation with police records than victim location estimates, and measures of offence location obtained from the survey and police records show highly similar geographical distributions. Importantly, the QSM models indicate that this does not come at the expense of data quality, with similar reliability coefficients across the measures of offence location and victim residence for the three crime types. Measures of reported crime do, however, show slightly lower reliability coefficients in the case of property crime, and substantially lower reliability for violent crime. In terms of reliability, there appears to be relatively little trade off when asking respondents to locate crime, while the impact in reliability may be larger when asking respondent whether they reported it to the police.

Whilst the reported crime estimates exhibit lower reliability, the MI-QSM results suggest that overall validity is actually highest amongst those offence location measures restricted to crimes reported to the police. In general, taking into account which crimes were reported to the police seems to decrease the systematic errors found in the original survey measures. This might be explained by the 'stabilising' effect of restricting crime measures to offences reported to the police, reducing the magnitude of the absolute differences between the volumes of crimes detected across different measures of crime. Whilst the unrestricted estimates of crime using offence location and victim residence are generally stable in time (as seen in QSM model results), there is less stability across measures. For example, victim residence estimates of crime are substantially larger than offence location measures, by contrast, measures of crimes reported to the police (both related to offence location and victim residence) are substantially lower and more similar to one another. However, unrestricted measures of offence location may still be preferable because they capture larger volumes of crimes experienced by victims and are more reliable.

The analysis also identifies which types of crime may be most difficult to accurately estimate. Both the QSM and MI-QSM results highlight that violent crimes have the lowest overall data quality. This may be linked to the relatively smaller number of violent crimes recorded in our

survey, though it may also relate to the inclusion of ‘threat of violence’ as a form of crime, which may be more prone to subjective interpretations than other crimes analysed. For example, the MI-QSM shows that the survey-based measures of violent crime used in previous research (i.e., based on victim residence and without correction for police reporting) have a quality indicator of around 0.5. This implies that around 50% of the observed variance is due to either random or systematic variance that is not related to the concept of interest. This proportion is smaller when using measures of offence location and measures restricted to crimes reported to the police. This is slightly less problematic for property crime, but in all three cases using offence location measures instead of the victim residence appears to contribute to an improvement in reliability, validity and resemblance to police records.

However, this work is not free of limitation. While we have studied three categories of crime defined by distinct spatial distribution patterns, these are likely to mask heterogeneity between specific crime types, in terms of their distribution in communities (Andresen and Linning 2012; Quick et al. 2018) and the reliability of offence-based and victim-based estimates of crime in place. For instance, it is likely that the measurement quality of victim residence measures of residential burglary will improve substantially compared with the larger category of household/vehicle property crime used here. In this paper, we aggregated crimes in larger categories to avoid an excess of zeros at the level of small areas. But future work should use alternative data sources to investigate the measurement properties of more detailed crime categories, as well as at smaller and larger spatial scales. Additionally, the MI-QSM makes an assumption about the stability of the traits of interest: a linear lag 1 autoregressive change in time. As a sensitivity check, we also pool all six years of data together and estimate a simpler Multitrait Multimethod model (Campbell and Fiske 1959; Saris and Andrews 1991). We follow a similar a procedure to decompose variation as in MI-QSM. The results (Figure A4 in the Appendix) are similar to those reported, giving us greater confidence in our results.

Overall, results indicate that there are potential gains to be obtained from using measures of offence location instead of victim residence, with apparently minimal impact on the reliability and validity of estimates. We do not find evidence of bias (e.g., from memory loss and non-recall) when asking victims about the place where crimes happened. Or at least we do not find that these potential issues are more problematic in measures of crime location than victim residence measures. This is observed not only when analysing crimes that tend to happen outside the area of residence (property personal and violence), but also when analysing property household and vehicle crimes that happen in victims’ area of residence to a larger extent. As a result, larger national crime surveys, such as the Crime Survey for England and Wales and the US National Crime Victimization Survey

should include measures of offence location in future waves. This will allow not only researchers but also policy makers to develop new techniques to estimate crime in place from survey data, thus potentially overcoming some of the sources of error that we know affect police-recorded crime statistics. Future research should also explore the effect of some issues relatively untouched here: (a) Do reliability and validity measure vary when using smaller or larger spatial scales? (b) Do these vary across rural and urban areas? (c) What is the effect of weights in this? And, can weights be used to mitigate some of the data quality issues described here? (d) What would happen if sample sizes were increased?

Appendix

Table A1. Questions about the location of crime in some of the main crime surveys.

Survey	Country	Round reviewed	Questions about place where crime happened
Crime Survey for England and Wales	England and Wales	2018/19	a) Can I just check, did it happen in this area (within 15 minutes walk of here)? b) Did it happen in England or Wales or did it happen somewhere else? c) Did the incident happen inside your own home or garage? d) Did the incident happen immediately outside or near your home? e) Did the incident happen in or near your place of work? f) Can you please tell me which option best describes where exactly the incident happened? (e.g., around a shop, around a school, in another street, at the home of a relative)
National Crime Victimization Survey	United States	2019	a) In what city, town, or village did this incident occur? b) Please specify the city, town, or village, in which the incident occurred. c) In what state did it occur? d) Did this incident happen...? (e.g., in your home, near your home, in a friend's home, at a commercial place, at school)
Scottish Crime and Justice Survey	Scotland	2018/19	a) Can I just check, did it happen in your local area - that is within about a 15 minute walk of your home? b) Did it happen somewhere else in Scotland, or did it happen outside Scotland? Did it happen in England or Wales or somewhere else? c) And where were you living when this occurred? d) Did the incident happen inside your own home or in a garage next to your home? e) Did the incident happen immediately outside your home? f) Did the incident happen in or near your place of work? g) Can you tell me where the incident happened? (e.g., around a pub, in a public car park, around a sports centre, online)
National Survey on Victimization and Perception of Public Safety	Mexico	2018	a) In what state did it occur? b) In what municipality did it occur? c) In which place did it occur? (e.g., in the street, at home, at my place of work, at a public area, public transportation)
New Zealand Crime and Victims Survey	New Zealand	2014	a) Where did the incident happen? (e.g., in own home, near victim's place of work, on the street, in a car park, pub)
National Urban Citizen Security Survey	Chile	2019	a) The last time, where did this happen to you or someone else in your household? Inside your home, near your home or building, in your neighborhood, at a different place in your municipality, at another municipality (which?), at another region (which?), at another country
General Social Survey - Victimization	Canada	2019	a) Where did this incident take place? (e.g., home and surrounding area, commercial establishments, street) b) Was this your place of work?
International Crime Victims Survey	International	2004-05	a) (The last time) did this happen at your own home/residence, near your own home/residence, elsewhere in your city or local area, at work, elsewhere in your country, or did it happen abroad?

Table A2. Sample size in Barcelona Victimization Survey.

	2015	2016	2017	2018	2019	2020	2015-16	2017-18	2019-20
Respondents	5,307	1,613	3,614	4,472	1,049	4,734	6,920	8,086	5,783
Crimes	3,166	997	2,678	3,752	1,207	5,227	4,163	6,430	6,434
Crimes geocoded	1,549	497	1,126	1,669	709	2,397	2,046	2,795	3,106
Mean respondents per area	72.70	22.10	49.51	61.26	14.37	64.85	94.79	110.77	79.22
Mean crimes geocoded per area	43.37	13.66	36.68	51.40	16.53	71.60	57.03	88.08	88.14
Response rate (%)	25.7	22.4	16.7	18.9	16.7	18.4	-	-	-

Figure A1. Visual representation of a quasi-simplex model, where y_t represents the observed score at point in time t , T_t represents the “trait” or “true score”, $\beta_{t,t-1}$ represents the stability, ζ_{t-1} represents the time specific trait and ϵ is the random error variance. For identification, the loadings (i.e., relationship between traits and observed variables) are fixed to 1.

Figure A2. Visual representation of the multi-item quasi-simplex model of violence. At each point in time t , the trait T is measured using the observed variables from the four “methods”, $\beta_{t,t-1}$ represents the stability, and the M factors represent the method specific variation that is stable in time. For identification and ease of estimation, the loadings (i.e., relationship between latent variables and observed variables) are fixed to 1. For ease of reading, we have excluded the residuals although they were also estimated in the model.

Figure A3. Mean estimates of crime for survey-based methods and years

Figure A4. Variance decomposition based on the MTMM using aggregated data for all the years.

Table A3. Variance estimates with standard errors and credibility intervals for latent variables in multi-item quasi-simplex

Dimension	Variable	Estimate	Post SD	Lower CI	Upper CI
Property (household/vehicle)	T1 (15/16)	0.56	0.10	0.40	0.79
	T2 (17/18)	0.20	0.05	0.13	0.30
