Are there non-linear relationships between alcohol consumption and long-term health?:

**Protocol for a systematic review of observational studies employing approaches to improve
causal inference**

ABSTRACT

Introduction There is a substantial literature finding that moderate alcohol consumption is protective against certain health conditions. However, more recent research has highlighted the possibility that these findings are methodological artefacts, caused by confounding and other biases. While modern analytical and study design approaches can enhance causal inference in observational studies, they are not routinely applied in research assessing the relationship between alcohol use and long-term health outcomes. The purpose of this systematic review is to identify observational studies that employ these analytical/design-based approaches in assessing whether relationships between alcohol consumption and health outcomes are non-linear. This review seeks to evaluate, on a per-outcome basis, what these studies find the strength and form of the relationship between alcohol consumption and health to be.

Methods and analysis Electronic databases (MEDLINE, PsycINFO, Embase and SCOPUS) were searched in May 2020. Study selection will comply with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines. Articles will be screened against eligibility criteria intended to capture studies using observational data to assess the relationship between varying levels of alcohol exposure and any long-term health outcome (actual or surrogate), and that have employed at least one of the pre-specified approaches to enhancing causal inference. Risk of bias of included articles will be assessed using study design-specific tools. A narrative synthesis of the results is planned.

Ethics and dissemination Formal ethics approval is not required given there will be no primary data collection. The results of the study will be disseminated through published manuscripts, conferences and seminar presentations.

Trial registration number International Prospective Register for Systematic Reviews (PROSPERO) number: CRD42020185861

Keywords: Systematic review; Alcohol; Abstinence; Causal inference; Risk factors; Protective factors

Strengths and limitations of this study

- This systematic review will be the first to identify those observational studies that best promote causal inference when assessing the relationship between alcohol and health outcomes, promising an important contribution to the literature
- A strength is that we will be searching for a broad, comprehensive range of analytical and design-based approaches to improving causal inference
- A further strength is the examination of a broad range of long-term health outcomes
- Given considerable differences among health outcomes and methodological approaches, analysis will be limited to narrative synthesis

INTRODUCTION

Despite the significant contribution of alcohol to the burden of disease worldwide [1], there is a substantial literature finding that low-to-moderate alcohol consumption is associated with improved health for a wide range of outcomes, including cardiovascular, cognitive, diabetic and mental health conditions, as well as mortality itself. Here, a 'J-shaped' relationship is common, where moderate consumption represents the nadir for risk, compared to a somewhat elevated risk for those who abstain from alcohol and a greatly increased risk for heavy alcohol drinkers.

However, dose-response relationships of this form are not common, and findings of protection against certain outcomes (e.g. cirrhosis of the liver) lack a plausible biological mechanism [2]. Such concerns have prompted scrutiny of biases in observational studies, raising the possibility that these J-shaped relationships are simply methodological artefacts [2,3]. Methodological limitations in this literature include confounding and reverse causality – issues that plague epidemiological research more generally in efforts to identify and estimate causal relationships – as well as selection biases and measurement errors more specific to this research question [3–5].

Many of these biases would be obviated by randomised controlled trials (RCT) in which participants are randomly assigned to different consumption levels and followed up on health outcomes. But due to practical and ethical considerations, no long-term RCTs have been conducted. In short-term interventional studies, moderate alcohol consumption has been found to promote beneficial changes in several biomarkers of cardiovascular health [6]. Similarly, a two-year RCT of diabetics found moderate wine consumption led to reduced cardiometabolic risk [7]. However, such benefits may only be transitory, and harms not yet apparent. Alcohol consumption can have complex cumulative and or/delayed effects [8]; without long-term follow-up, these cannot be observed.

Instead, recent efforts have focused on mitigating biases in observational designs, with a focus on the impact of methodological decisions regarding data collection and analysis. There is acknowledgement that such decisions – e.g. which covariates to measure, how exposure levels are defined and compared, which population to sample, what model to use – can have substantial effects on

conclusions about the strength and form of a relationship [9,10]. Tools available in the study planning phase can improve some of these methodological decisions. For example, causal diagrams can be created to identify confounders as well as possible selection bias. Steps implemented post-main analyses can help to determine the robustness of findings across alternative methodological decisions ('sensitivity analyses'), or in the face of potential unmeasured bias ('bias analysis'). Additional checks for robustness across populations with different underlying confounding structures ('cross-cohort comparison') or across different methodological approaches ('triangulation') can also strengthen causal conclusions [11].

Modern epidemiological developments in data analysis and alternative study designs, however, may have the most potential to mitigate the limitations of existing research, particularly in addressing confounding. Causal inference in conventional observational designs (e.g. prospective cohort studies) can be enhanced with modern data analysis methods. These include propensity scores (estimating the exposure mechanism as a data pre-processing step prior to main analyses), and 'G-methods' (which can account for time-varying variables). Doubly robust methods incorporate estimation of both the exposure and outcome mechanisms, so only require correct specification of one of these models to produce accurate estimates of an exposure's effect [12]. Importantly, these methods still rely on all relevant confounders being measured, and measured without error (i.e. residual confounding is still possible). Other analytical tools that may enhance causal inference include fixed effects regression (focussing exclusively on within-subject variation, thus avoiding confounding) and causal mediation (identifying the mechanism/s through which an exposure may be exerting a causal effect).

Alternate observational study designs represent another approach, often eschewing the need to accurately identify and measure confounders altogether. Natural experiments, including those based on instrumental variables, mimic the random allocation of an RCT, bypassing the problem of confounding, and guarding against reverse causation. Genetic instrumental variable designs such as Mendelian Randomisation (MR) show particular promise because of their ability to find proxies for alcohol consumption, and are increasingly popular in this research area. Family-based designs can also mitigate unmeasured confounding (to the extent to which relevant covariates are shared), as can

negative control designs [13]. Table 1 provides an overview of these analytical and alternative design methods for improving causal inference.

Table 1. Description of methods to enhance causal inference of interest for this systematic review

Method	Relevant sub-methods	Description
Analytical methods applied to traditional longitudinal study designs		
Propensity scores (PS) [14,15]	Covariate balancing propensity scores (CBPS)	<ul style="list-style-type: none"> -The PS is a single value reflecting the probability of exposure for an individual given their values on all relevant covariates -PS generation occurs as a data 'pre-processing' step prior to main analysis -Usually generated via logistic regression -Once generated, the PS can be used for matching, stratification, weighting (using inverse probability of treatment weights), or as a covariate for adjustment in regression
G-methods [16–19]		<ul style="list-style-type: none"> -A family of methods intended for use with time-dependent variables -Developed as a solution to the problem of time-varying covariates affected by past exposure, including those that act as both confounders and mediators over time -The three G-methods are the G-formula, marginal structural models, and G-estimation, each relying on its own modelling assumptions
	G-formula (aka G-computation or G-standardisation) [12,17,19,20]	<ul style="list-style-type: none"> -First models relationship given observed data (using actual exposure for each individual), and then predicts outcomes under counterfactual exposures, with the difference taken as the causal effect -Is a generalisation of standardisation (conditioning on covariates and then marginalising) that accounts for dynamic variables by considering covariate distribution over follow-up time
	Marginal structural models (MSMs) [17,19,20]	<ul style="list-style-type: none"> -Use weights based on inverse probability of exposure at each time point to create a pseudo-population where each combination of covariates is equally present in each exposure condition -Using these weights, MSMs then estimate the causal effect -The most popular of the G-methods
	G-estimation of structural nested models [17,18,20]	<ul style="list-style-type: none"> -At each wave assesses the relationship between exposure and likelihood of outcome given covariates, adjusting for exposure and covariate values from past waves, thus accounting for dynamic confounders affected by past exposure -Considered semi-parametric in that mean counterfactual outcomes under no exposure are unspecified
Doubly robust methods [12]	Targeted maximum likelihood estimation; Augmented inverse probability weighting	<ul style="list-style-type: none"> -Incorporates both an estimation of the outcome mechanism (as in G-formula or regression adjustment) and the exposure mechanism (as in propensity scores)
Fixed effects regression [21–23]		<ul style="list-style-type: none"> -A technique developed in the econometrics literature for use with longitudinal data with repeat outcome measurements, only using information on within-subject variation, thus controlling for all time-invariant sources of confounding -Treats time-invariant characteristics that differ between individuals as fixed parameters (unlike in mixed models), allowing estimation of parameters of interest net of stable confounders -Each participant serves as own control
Causal mediation analysis [24–26]		<ul style="list-style-type: none"> -Integrates traditional mediation analysis (which separately estimates total effect of exposure on outcome, indirect effect via mediators, and direct effect unexplained by mediators) with the potential outcomes framework to allow for exposure-mediator interaction and non-linear relationships (i.e. is a non-parametric method) -Uses the concepts of 'controlled direct effect', 'natural direct effect', and 'natural indirect effect' -Makes explicit underlying assumptions related to unmeasured confounding, and encourages sensitivity analyses to test robustness to assumption violations
Alternative observational study designs		

Method	Relevant sub-methods	Description
Natural experiments [11,27–29]		<ul style="list-style-type: none"> -Mimic RCTs by exploiting exogenous events that are truly randomised/approximate random assignment -Differ from true experiments in that exposure is not assigned by the researcher -Assignment may be as a result of naturally occurring phenomena (e.g. a weather event), or of human intervention implemented for reasons other than the research question (e.g. army draft lottery)
	Standard natural experiments	-Natural experiments where individuals are as-if/randomly assigned to exposure and control groups
	Instrumental variable analysis	<ul style="list-style-type: none"> -Assesses the relationship between an as-if/ randomly assigned <i>proxy</i> for the exposure of interest and the outcome -A valid instrumental variable must be associated with the exposure of interest, be independent of confounders of the exposure-outcome relationship, and should affect the outcome only via the exposure
	Genetic instrumental variables	<ul style="list-style-type: none"> -Subset of instrumental variable analysis using genetic variants as proxies for exposure -The most prominent technique is Mendelian Randomisation
Quasi-experiments [27]		-Like natural experiments, exploit exogenous events to assess relationships between exposures and outcomes, but lack random or as-if random assignment
Family-based designs [11,28]	Twin studies; Sibling comparison	-By comparing genetically related participants discordant for the exposure of interest, accounts for confounding from genetic or shared environmental sources
Negative controls [13,28]	Negative control exposures; Negative control outcomes	<ul style="list-style-type: none"> -Have the same confounding structures as the exposure-outcome relationship of interest, but lack a plausible causal mechanism -If association is greater for the relationship of interest than for the negative control, a causal relationship is likely; if not, suggests confounding/other shared biases responsible -May take the form of a negative control exposure or a negative control outcome

Rationale

The functional forms of many of the relationships between alcohol use and specific health outcomes are currently unclear. Several recent pooled analyses and reviews have failed to provide evidence for J-shaped relationships, finding monotonically increasing dose-response relationships with most health outcomes, including most, if not all, cancers [1,30]. Yet certain cardiovascular and diabetic conditions are consistent exceptions [1,30], and new, rigorous individual studies that consider the impact of methodological decisions continue to find J-shaped relationships for other outcomes, e.g. mortality [31]. Whether these findings reflect truly causal relationships remains an open question.

The state of the evidence base may be due to the fact that, while some of the discussed analytical and design-based methods are becoming more popular in health research [19], they are not frequently employed in this specific research area (with calls for greater implementation [32]). Despite the many

reviews focusing on the relationship between alcohol use and various health outcomes, analytical methods to counter confounding are rarely a focus. Similarly, reviews of observational research tend to search exclusively for studies with traditional designs (e.g. cohort studies), meaning findings from novel study designs are not integrated. As such, the planned review, focusing on those studies that best promote causal inference, comprises an original and important contribution.

Objective

The objective of this review is therefore to identify all observational studies that have employed the aforementioned analytical or design-based approaches (see Table 1), and to synthesise their findings on the strength and functional form (i.e. support for non-linearity) of the relationships between levels of alcohol consumption and various long-term health outcomes (or surrogates) in humans.

METHODS

This protocol complies with the Preferred Reporting Items for Systematic Reviews and Meta-Analysis Protocols (PRISMA-P) statement [33], the checklist for which can be found in the online Supplementary File. This protocol has been registered with the PROSPERO International Prospective Register of Systematic Reviews of the University of York (CRD42020185861). Reporting of the systematic review will be informed by Preferred Reporting Items for Systematic Review and Meta-Analysis (PRISMA; [34]).

Search strategy

Electronic databases (MEDLINE, PsycINFO, Embase and Scopus) were searched in May 2020 for peer-reviewed, English-language journal articles, with no restrictions on date range. Relevant grey literature returned by Scopus will also be considered. The search strategy was designed to capture all studies using observational data to assess the relationship between varying levels of alcohol exposure and any health outcome, and that have employed at least one of the pre-specified approaches to improving causal inference.

Searches ran a combination of MeSH or other controlled vocabulary terms as well as free text words. Five groups of terms are used in the search strategy, relating to: 1) Alcohol; 2) Levels or patterns of

drinking 3) Observational, longitudinal studies; 4) Approaches to improve causal inference that are used in conjunction with observational, longitudinal study designs; and 5) Approaches to improve causal inference that may be considered their own study designs. These concepts are combined with the following logic: 1 and 2 and ((3 and 4) or 5). Search terms were adapted from recent systematic reviews and from keywords/indexing of a set of key eligible papers known to the study authors. These terms were iteratively refined to improve sensitivity by cross-checking results against the set of key papers. The MEDLINE search terms are provided in the online Supplementary File.

Cross-checking of reference lists of relevant, retrieved publications will be used to supplement the database searches.

Eligibility criteria

Eligibility criteria for this review are spread across population, exposure, comparator, outcome and study design components of the publications under consideration (PI/ECOS).

Population

Only human studies will be eligible for inclusion. While there are no other restrictions on eligible populations, alcohol consumption must be assessed in the same individuals to which the health outcome/s accrue (i.e. the relationship between an individual's alcohol consumption and the health of others is beyond the scope of this review).

Exposure

The exposure of interest is level of alcohol consumption (volume over a certain period) or level and pattern of consumption (incorporating information on frequency or presence of heavy episodic drinking). There must be a non-drinking reference group and at least two other levels of consumption (or equivalent categorical structure in instrumental variables designs allowing for tests of non-linear relationships). While it is anticipated that the construction of these categories will vary (e.g. different criteria for volume/frequency of consumption, differential use of lifetime and current consumption),

all will be eligible for inclusion. Differences between studies in drinking category composition will be considered during data synthesis.

Comparator

Reference groups should comprise abstainers/non-drinkers, but reference groups partly or solely comprised of occasional drinkers will also be accepted. Non-drinker reference groups that include former drinkers will also be accepted. Differences between studies in reference group composition will be considered during data synthesis.

Outcomes

Studies on the association between alcohol consumption and health outcomes have reported J-shaped relationships for a wide range of long-term conditions and their surrogates (e.g. biomarkers). The focus of this review is to examine how approaches to improving causal inference in observational research have been used across the entirety of the literature, regardless of outcome type. Given common targets of study in the broader literature, it is anticipated that papers included in this review will include the following outcomes: cancer (and subtypes), cardiovascular disease (and subtypes), cognition and dementia, mental health conditions, diabetes, and cause-specific or all-cause mortality, among others. Short-term or acute conditions such as injury, acute exacerbation of mental illness, sexually transmitted diseases, alcohol-drug interactions and sexual function will be excluded.

Study design

Observational studies assessing the relationship between varying levels of alcohol consumption and any health outcome will be eligible. Studies must have tested whether this relationship was non-linear and must have employed at least one of the pre-specified analytical/design-based approaches.

Incorporating feedback from academics with expertise in causal inference methods, the approaches of explicit interest chosen for this review have been clearly defined a priori and have been recognised and employed in recent years for their potential to enhance causal inference. Specifically, these are: propensity scores, the G family of methods, targeted maximum likelihood estimation and other doubly

robust methods, fixed effects regression, causal mediation analysis, standard natural experiments, MR and other instrumental variables, quasi-experiments, family-based methods, and negative controls.

Conventional observational studies employing analytical methods to promote causal inference must be cohort or case-control designs and must be longitudinal, with alcohol consumption measured at least once at a time point preceding measurement of health outcome/s (studies employing MR/other natural experiment approaches will be eligible even if not longitudinal). Systematic reviews/meta-analyses, interventional studies, and animal studies will be excluded.

Study selection

All citations will be imported into Endnote [35] and deduplicated. Citations will then be uploaded to Covidence [36], which will be used to facilitate screening. Titles and abstracts returned by the database searches (and any additional papers identified by hand) will be screened independently by one reviewer (RV), with a second reviewer (JW) to screen a random selection of 25% of the titles and abstracts. Full-text articles of potentially eligible articles will be independently assessed by two reviewers (RV and JW). If at any stage discrepancies cannot be resolved through discussion and consensus, a third reviewer (LM) will be consulted.

Data extraction

A standardised pre-piloted data extraction form will be used, with extraction performed independently by two reviewers (RV and JW). Study authors will be contacted if further information is required.

Data extracted will include:

1. *Study information*: author/s, year of publication
2. *Participant characteristics*: sample size, study setting, mean age at baseline, relevant eligibility criteria, cohort name (if applicable)
3. *Exposure/comparator characteristics*: number and spread of measurement occasions, number and nature of drinking consumption/abstention categories

4. *Study design and analysis*: approach/es of interest used (i.e. study design of interest, combination of traditional study design and analytical method of interest), any additional statistical tests employed, any additional measures taken to enhance causal inference (i.e. causal diagrams or tests of robustness), covariates/confounders included in models or otherwise accounted for
5. *Outcomes*: health outcome/s assessed and whether these are binary or continuous
6. *Results*: findings on the strength and form of the relationship between alcohol and health

Again, if at any stage discrepancies cannot be resolved through discussion and consensus, a third reviewer (LM) will be consulted.

Risk of bias assessment

Assessment of bias depends on study design and methodology. As a range of designs and methodologies are expected in the included studies, several existing risk of bias assessment tools will be used. Quality of cohort and case-control studies will be assessed using the relevant Newcastle-Ottawa Scales (NOS; [37]). Recently developed risk of bias tools specific to Mendelian Randomisation studies, natural experiments, and family-based methods [38] will be used and adapted where appropriate. One reviewer (RV) will apply the assessment tools to all included studies, with a second reviewer (JW) assessing a random 25% of the studies to establish scoring accuracy.

Data synthesis

Descriptive narrative synthesis will be performed. The relationships between alcohol and different health outcomes vary due to mediating causal mechanisms, meaning they are not comparable. As such, in addressing what the included studies find on the relationship between levels of consumption and health, synthesis will be conducted on a per-outcome basis. The heterogeneity of the different analytical approaches means they are not suited to quantitative synthesis.

Assessment of evidence quality

Popular tools to assess the body of evidence gathered, such as Grading of Recommendations, Assessment, Development, and Evaluation (GRADE; [39]), are inappropriate here. Given initial 'low quality' ratings are automatically assigned to observational studies, GRADE is of limited use for

exposures that do not lend themselves to RCTs [40,41] (including alcohol consumption [42]).

Additionally, these tools are intended to rate *bodies* of evidence – such ratings are ill-suited to this review given it is intentionally restricted to a subset of the literature. Consistent with recent reviews focusing on observational studies employing novel causal inference approaches, this review will limit formal assessment of evidence quality to risk of bias [38,43].

Patient and public involvement

As this is a review of existing published studies, there will be no patient or public involvement in this research.

ETHICS AND DISSEMINATION

Formal ethics approval is not required given there will be no primary data collection. The results of the study will be disseminated through published manuscripts, conferences and seminar presentations.

CONCLUSION

This paper presents the protocol for a systematic review of observational studies that assess the relationship between levels of alcohol consumption and various health outcomes, and that employ certain pre-specified analytical or design-based features to enhance causal inference. This will be a novel perspective through which to examine the literature on whether moderate alcohol consumption is protective, focusing on those studies that best promote causal inference from observational research. The presumption that the associations found between moderate alcohol consumption and good health reflect a causal relationship significantly impacts burden of disease estimates, safe drinking guidelines and public health policy [44,45]. The importance of the proposed review will therefore lie in helping to establish whether such findings are truly causal.

Authors' contributions: RV is the guarantor of the review. RV, MS, TS and LM conceptualised the study and developed the study design and protocol. RV wrote the first draft of the manuscript. All authors read, revised and approved the final manuscript.

Funding RV is funded by the National Health and Medical Research Council (GNT1190255) and the University of Sydney.

Acknowledgements The authors would like to thank Jessica Hughes, librarian at the University of Sydney, for assisting with the literature search.

Competing interests None declared.
